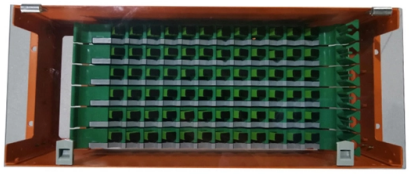
What are the full-process switch access methods



Overview

Switching is a technique for establishing communication paths and transferring data between devices in a computer network.

Key Takeaways

The full-process switch access method, also known as process switching, is a packet forwarding technique where each packet is individually processed by the router's CPU, involving complete routing table lookups and header modifications.

Overview

The full-process switch access method is one of the earliest and most robust packet switching techniques used in routers and Layer 3 switches. In this method, every incoming packet is handled entirely by the CPU, which makes forwarding decisions based on the routing table and performs all necessary header modifications before sending the packet to the outgoing interface.

Step-by-

Step Process

Packet Reception: The router receives a packet on an inbound interface and stores it in memory. Routing Lookup: The CPU performs a lookup in the global routing table (Routing Information Base, RIB) to determine the best path to the destination IP address. Header Processing: The router removes the Layer 2 Ethernet frame header, decrements the IP Time-to-Live (TTL) value, recalculates the IP header checksum, and rewrites the source and destination MAC addresses for the outgoing interface.

Forwarding: The processed packet is sent out through the appropriate interface toward the next-hop router or destination.

CP

U Involvement: Each packet is independently processed, which allows for load sharing across multiple links but increases CPU utilization and can lead to out-of-sequence packet delivery.

Advantages and Limitations

Advantages: Highly flexible and robust, capable of handling complex routing decisions. Useful for packets that cannot be handled by faster switching methods, such as those requiring special processing or policy enforcement. Limitations: High CPU usage because every packet is processed individually.

Slower than fast switching or Cisco Express Forwarding (CEF), making it less suitable for high-volume traffic. Potential for packets to arrive out of sequence, requiring additional processing at the destination. Comparison with Other Switching MethodsFast Switching: Uses a cache to store forwarding decisions for subsequent packets in the same flow, reducing CPU load after the first packet.

Cisco Express Forwarding (CEF): Builds Layer 2 and Layer 3 tables in hardware, allowing packets to be forwarded at wire speed with minimal CPU involvement. Use CasesFull-process switching is now primarily used as a fallback mechanism when faster methods like CEF cannot handle certain packets, such as those requiring special routing, policy checks, or punted packets. It ensures that all packets are eventually forwarded correctly, even if at a slower rate.
